(57) **ABSTRACT**

Systems and methods are provided for downloading battery data to a mobile communication device. A system for downloading battery data to a mobile communication device may include a mobile communication device and a data server. The mobile communication device may be configured to monitor a battery operating condition and to receive a battery profile, the battery profile including battery data for use by the mobile communication device to calculate battery status information. The data server may be used for storing battery data, the data server being configured to receive the battery operating condition from the mobile communication device and, based on the battery operating condition, send the battery profile to the mobile communication device.

METHOD AND APPARATUS FOR DYNAMIC BATTERY MANAGEMENT CONTROL IN A MOBILE COMMUNICATION DEVICE

CROSS-REFERENCE TO RELATED APPLICATION

This is a continuation of U.S. application Ser. No. 12/393, 146, filed Feb. 26, 2009, which is hereby incorporated herein by reference.

FIELD

The technology described in this patent document relates generally to systems and devices that monitor a battery. More particularly, systems and methods are provided for monitoring the operating characteristics of a battery.

BACKGROUND

Modern mobile communication devices, such as cell phones, PDAs, etc., typically use a rechargeable battery. The characteristics of the battery, including battery capacity versus voltage, impedance at various temperatures, etc., are known during production of the battery and may subsequently be programmed into the mobile communication device. These characteristics are typically used by the mobile communication device for calibration, or for providing battery status and usage information to the user of the device. If the battery is updated or modified after production, however, then the information programmed into the mobile communication device may no longer be applicable or provide accurate information to the user. Furthermore, changes in the environment of the battery, or the age of the battery, can affect the accuracy of the characteristics programmed into the mobile communication device.

SUMMARY

In accordance with the teachings described herein, systems and methods are provided for downloading battery data to a mobile communication device. A system for downloading battery data to a mobile communication device may include a mobile communication device and a data server. The mobile communication device may be configured to monitor a battery operating condition and to receive a battery profile, the battery profile including battery data for use by the mobile communication device to calculate battery status information. The data server may be used for storing battery data, the data server being configured to receive the battery operating condition from the mobile communication device and, based on the battery operating condition, send the battery profile to the mobile communication device.

BRIEF DESCRIPTION OF THE DRAWINGS

FIGS. 1-3 are block diagrams depicting example systems for determining the status of a rechargeable battery.

FIG. 4 is an example battery measurement subsystem for a mobile communication device.

FIG. 5 is a flowchart of an example battery capacity processing method.

FIG. 6 is an example data server for storing battery profiles.

FIG. 7 is an example data server utilizing a battery model to generate a battery profile.

FIG. 8 is an example data server utilizing a battery model and a battery table selector.

2

FIG. 9 is a flowchart of an example method for downloading battery data on a mobile communication device.

FIG. 10 is a block diagram of an example mobile communication device.

DETAILED DESCRIPTION

FIG. 1 is a block diagram depicting an example system 100 for determining the status of a rechargeable battery. The system includes a mobile communication device 102 and a data server 110. The mobile communication device 102 includes a rechargeable battery 104, a battery management subsystem 106, and an operating system 108. It should be understood, however, that the system 100 may also be used with other types of systems or devices that utilize a rechargeable battery.

The system 100 may be used to wirelessly download battery data to a mobile communication device 102. The mobile communication device 102 uses information stored in a battery profile, including operating conditions gathered from a battery 104 and battery characteristics preloaded during manufacture, to update the status of the battery to the user. As conditions of the mobile communication device 102 and the battery 104 change, the mobile communication device 102 may need different battery data to accurately determine the status of the battery 104. For example, deterioration of the battery 104 is not a factor that a manufacturer typically preprograms into the mobile communication device 102 to use in calculating the battery status. Another example is a wide change in the ambient temperature of the battery 104 that the mobile communication device may not be capable of handling. When those conditions change during the life of the battery 104, the operating system 108 cannot account for the changed conditions using a battery profile that was loaded during the manufacturing process.

To account for changed conditions, the mobile communication device 102 may be programmed with one or more triggering events 114 that cause the mobile communication device 102 to request updated battery data from a data server 110. A triggering event 114 that prompts the operating system 108 to send operating conditions 112 to the data server 110 may include a change in ambient temperature, a power-up of the mobile communication device, a new charge cycle of the battery, a low battery alert, and a request by the user of the mobile communication device. Following the triggering event 114, the mobile communication device 102 sends its current battery operating conditions 112 to the data server 110 so the mobile communication device 102 can receive an updated battery profile 116.

The data server 110 contains information used to characterize a battery in the form of battery profiles. The data server 110 receives the battery operating conditions 112 from the mobile communication device 102 and wirelessly transmits the corresponding battery profile 116 back to the device. The mobile communication device 102 may replace its existing battery profile with the battery profile 116 received from the data server 110. This new battery profile can be used to update the status of the battery on the mobile communication device. A benefit to updating a battery profile on the mobile communication device is that the information will be more applicable to the present condition of the battery. Thus, more accurate information will be available that allows the mobile communication device 102 to more efficiently use the battery 104 and provide more reliable information to the end user.

The mobile communication device 102 includes a rechargeable battery 104, a battery management subsystem 106, and an operating system 108. The battery management subsystem 106 may include one or more processing devices,

3

such as a microprocessor or a DSP, and may also include one or more sensor devices for detecting operating conditions **112** of the battery **104**. For example, the battery monitoring subsystem **106** may include sensor devices that allow the battery monitoring subsystem **106** to provide the operating system **108** with the ambient temperature of the battery **104** and the state of charge of the battery **104** to the operating system **108**. The battery monitoring subsystem **106** may also include other devices or software to monitor the cycle life of the battery. The operating system **108** controls the overall operation of the mobile communication device **102** and may include one or more microprocessors, DSPs, or other processing devices. Operating conditions received at the operating system **108** are used to update the battery status **114** of the mobile communication device **102**.

Battery status **114** may include the fully charged capacity of the battery (the total capacity capable in the battery), the current usable capacity of the battery (the present capacity available in the battery), and the equivalent series resistance of the battery. The battery status **114** of the mobile communication device is based upon combinations of preloaded battery characteristics and operating conditions **112**. These combinations are referred to as battery profiles, and are described in more detail below in reference to FIG. 5.

The data server **110** is configured to receive battery operating conditions **112** from a mobile communication device **102** and send battery data to the mobile communication device **102** based on the received operating conditions **112**. The data server **110** stores battery data that includes battery profiles, which are linked to a corresponding battery and its battery operating conditions. Battery profiles include battery tables that contain battery operating conditions and battery characteristics. Each battery table includes a battery operating condition that is stored in relation to another battery operating condition or in relation to a battery characteristic. For instance, one battery table may include the temperature of the battery in relation to the equivalent series resistance of the battery (e.g., see battery table **332** in FIG. 5). The combination of the two elements allows the mobile communication device **102** to update the status of the battery **104**. A battery profile may include any number of battery tables depending on the requirements of the mobile communication device **102** requesting the information. A complete battery profile, however, will contain each battery table that a particular mobile communication device uses to determine the battery status of its battery.

After the data server **110** receives the battery operating conditions **112**, it selects the battery profile **116** that corresponds to the battery operating conditions **112**. The data server **110** sends the battery profile **116** to the mobile communication device **102**, which uses the battery profile **116** to calculate the battery status **114**. The received battery profile **116** is used until the operating system **108** receives another triggering event **114**, and subsequently receives another battery profile **116**.

FIG. 2 depicts another example system for determining the status of a rechargeable battery. This system is similar to the system depicted in FIG. 1, except that the data server **110** returns only a selected battery table(s) **120**, instead of the entire battery profile. As shown in FIG. 2, the operating system **108** sends a battery table selector **118** to the data server **110** to request only a portion of a battery profile. The battery table selector **118** may either be sent at a time before or after the operating conditions **112** are sent to the data server **110**, or at the same time. The data server **110** uses the battery table selector **118** to select a specific battery table **120** from a battery profile that corresponds to the operating conditions

4

112. For example, if the triggering event **114** is a change in ambient temperature, the battery table selector **118** may direct the data server **110** to send only the one or more battery tables **120** that correspond to temperature, instead of sending the entire battery profile. The operating system **108** receives the one or more battery tables **120** and replaces only those corresponding portions of the battery profile stored on the mobile communication device **102**. By replacing only a selected portion of the battery profile, the amount of processing is reduced on the mobile communication device and less network bandwidth is used.

FIG. 3 illustrates yet another example system for determining the status of a rechargeable battery. In this example, the mobile communication device **102** automatically triggers the data server **110** to transmit a current battery profile at predetermined intervals **114**. Further, the interval at which an updated battery profile is requested may be set so that the combination of receiving a battery profile, or battery tables, and battery life is optimized. The shorter the interval set to receive information from the data server, the larger a strain it will have on the battery **104** and on the wireless network. A shorter interval, however, will receive more frequent battery profiles, or tables, and provide for a more exact battery status. Thus, the optimized predetermined interval **114** may be calculated to provide for the most frequent amount of information received from the data server **110**, without sacrificing a significant portion of battery life.

FIG. 4 illustrates an example battery measurement subsystem **106** for a mobile communication device that can be utilized in a system to download battery data to the mobile communication device, such as the systems shown in FIGS. 1-3. The battery measurement subsystem **106** may receive a selection command from the operating system **108** and send a measurement value (i.e., a value indicating the battery state) to the operating system **108** in response to the selection command.

The battery measurement subsystem **106** includes a battery **104** that powers the mobile communication device. The battery **104** includes a cell **212**, a battery temperature sensor **214**, and an identification block **216**. The identification block **216** may enable the operating system **108** to determine the type of battery **210**.

The battery temperature sensor **214** provides a battery temperature signal that indicates the temperature of the battery **104**. A battery temperature signal conditioning block **224** conditions the battery temperature signal to generate the signal Tbat. Conditioning functions performed by the signal conditioning block include filtering, scaling and/or amplifying. The signal conditioning block **224** may also perform other functions, such as providing bias required by the identification unit **216**, multiplexer **240** and/or the analog to digital converter **250**. After the Tbat signal is generated, it is coupled to an input of the multiplexer **240** for selection by the microprocessor **138**.

A cell signal conditioning block **222** monitors the voltage and current of the cell **212**. The cell signal conditioning block **222** provides a conditioned battery voltage signal, Vout+, and a conditioned battery current signal, I1, to the inputs of the multiplexer **240** for selection by the operating system **108**.

In one embodiment, the cell signal conditioning block **222** may not provide a battery current. In this case, the current may be obtained indirectly by measuring TX power and by detecting other device states that affect current, such as operation of backlight, buzzer and LED (within the other device subsystems **228**), as described below.

The TX power sensor **242** detects the transmit power of the transmitter **114** (FIG. 1), and inputs the transmit power to the

TX power signal conditioning block **232**. The TX power conditioning block **232** performs typical conditioning functions, such as filtering, scaling or amplifying, as well as providing a bias that may be required by the TX power sensor **242**, multiplexer **240** and/or the analog to digital converter **250**. The TX power conditioning block **232** generates the TXp signal that is coupled to the multiplexer **240** for selection by the operating system **108**.

The incremental current consumption of the additional devices, such as backlight, buzzer and LED within the other device subsystems **228**, are pre-characterized and their values are stored in flash memory **124** according to the states of these devices. The software that runs on the operating system **108** controls the operation of these device states and, therefore, the states can be detected and corresponding incremental current consumptions by these devices can be included in the processing.

A board temperature sensor **244** provides a board temperature signal, Tbrd, that indicates the temperature of the printed circuit board of the transceiver. This signal is conditioned by the board temperature signal conditioning block **234** and coupled to an input of the multiplexer **240**.

The identification block **216**, provides the identification signal Battery ID that is conditioned by the identification signal conditioning block **226** and input to the multiplexer **240**.

In operation, multiplexer **240** responds to the selection signal sent by the operating system **108** to drive a select measurement signal such as: Tbrd, Vout+, I1, TXp, Tbat or the battery ID, through the analog to digital converter **250**. The analog to digital converter **250** digitizes the signal output from the multiplexer **240** and sends the digital representation of the measurement value to the operating system **108**. For example, if the operating system **108** requests a battery ID, a predetermined selection command assigned to the battery ID is transmitted to the multiplexer **240** of the battery measurement subsystem **106**. The multiplexer **240** may use this command to switch the battery ID input to the output of the battery measurement subsystem **106**.

FIG. 5 includes a flowchart of an example battery capacity estimation method using a battery profile. A program for performing this method may, for example, be included in a software module in the mobile communication device of FIG. 1. As an example, FIG. 5 depicts a battery capacity estimation software module **124C**, which is included in other software modules **124N** and may be stored in a flash memory **124**.

In operation, at step **310**, the method samples the battery measurements that include various operating parameters of the battery, such as temperature (T), loaded voltage (V_{load}), current (I1), and transmit power (TXp). When the method is used in cooperation with the subsystem of FIG. 4, this step may include instructing the operating system **108** to send at least one selection signal to the multiplexer **240** of the battery measurement subsystem **106**. The operating system **108** then reads the selected measurement for each selection signal sent at the output of the analog to digital converter **250**.

At step **320**, the battery measurements sampled at step **310** are pre-processed to provide intermediate results used in the battery capacity processing step **350**. In preprocessing, at least one battery profile **330** is used to translate the measurement to a corresponding value (e.g., temperature to resistance).

Battery profile **330** may support a battery that a user may plug in and use on a mobile communication device. Each battery profile **330** identifies a given battery pack. In other words, for a specific battery there corresponds a specific battery profile **330**.

As described below, values of the table in the profile **330** are dependent on the maker/model/version/batch of the battery. The values are determined at the time of battery manufacture and are loaded into the profile table **330**. During use in the data server, the values may be updated through calibration between the mobile communication device and the data server.

Each battery profile **330** may include multiple tables that profile a particular battery. These tables may include the Equivalent Series Resistance (ESR) versus battery temperature (Tbat) **332**, the current (I) versus transmit power (TXP) **334**, the battery voltage threshold value at which the radio shuts off (VROFF) stored as a function of board temperature (Tbrd) **336**, the battery capacity (CAP) as a function of unloaded voltage (V) **338**, the battery capacity compensation factor at temperature Tbat **340**, and the ESR compensation factor at temperature Tbat **342**. This is illustrated as Profile 1 **330**.

One example of an intermediate result of the pre-processing step **320** may include ESR_VS_T **332**. A table translates the temperature to resistance through linear interpolation in the battery capacity estimation method. The table size may, for example, be eight elements that are equally spaced between -20° to 75° C., unsigned. This interpolation can be expressed by:

$$ESR(Tbat) = \text{Linear_interpolate}(ESR_VS_T, Tbat);$$

where Linear_interpolate (ESR_VS_T, Tbat) represents the linear interpolation of the table ESR_VS_T at temperature Tbat. The values stored in the table are the average values obtained by characterization of the battery pack upon manufacture.

The battery capacity processing **350** takes place using the intermediate results of the above-described preprocessing step **320**. The result of step **350** is the battery status info that is used to update the battery status of the mobile communication device.

With reference to FIG. 6, an example data server **110** is depicted. The data server **110** is configured to store battery data in a table-like format with columns for a battery identifier, battery operating conditions, and battery profiles. The data for the battery operating conditions is stored in ranges, so that corresponding operating conditions received by the data server can be matched within a certain range of data. Other methods for storing data may also be used, such as storing specific values for each battery operating condition, and subsequently matching the received battery condition to the closest value in the table.

In the example shown, the data server **110** stores battery identifiers that correspond to a plurality of batteries that may be used in a mobile communication device. For each battery, there will correspond a plurality of battery operating conditions, such as temperature, current load, cycle life of battery, and state of charge. For each different combination of battery operating conditions with a battery identifier, there will correspond a battery profile. An example of a battery profile is shown as Profile A **330**.

Based on the number of operating conditions, the battery profile **330** contains battery tables relating to a plurality of conditions. Profile A **330** shows seven battery tables as only one example. The method for calculating battery tables within a battery profile is described above in reference to FIG. 5. Depending on the data sent by the mobile communication device to the data server, the data server may either return the entire battery profile or one or more battery tables. If the data server does not receive a battery table selector from the mobile communication device, an entire battery profile will

7

be sent. If the data server receives a battery table selector, then the data server will only return those battery tables specified by the battery table selector.

In another embodiment, the data server 110 includes a battery model 400, as shown in FIG. 7. In operation, the battery model 400 receives one or more operating conditions 112 from the mobile communication device 102. The battery model 400 utilizes the one or more operating conditions to generate one or more battery profiles. Because the battery model 400 does not store each battery profile in relation to battery operating conditions, the battery model 400 does not require as much storage capacity as the example data server in FIG. 6. Thus, by generating a battery profile for each request received from a mobile communication device, the battery model 400 may provide for a more efficient system.

In another embodiment, the data server 110 includes a battery model 400 and a battery table selector module 402, as shown in FIG. 8. The battery model 400 operates in the same manner as described above in relation to FIG. 7. The battery table selector module 402 receives a battery table selector signal from the mobile communication device 102 that specifies a specific battery table to be sent to the mobile communication device. The battery model 400 may produce the entire battery profile, but the battery table selector module 402 specifies which table, or tables, in the profile will be sent to the mobile communication device 102. Therefore, the mobile communication device 102 does not receive an entire battery profile, and can only replace those corresponding tables in its pre-existing battery profile. This selection process reduces the processing requirement on the mobile communication device and network congestion.

FIG. 9 is a flow diagram of an example method for downloading battery data on a mobile communication device. At step 500, the operating system of the mobile communication device obtains battery operating conditions from the battery measurement subsystem. The battery operating conditions are gathered by the battery measurement subsystem of the mobile communication device. If a triggering event occurs, then the operating system sends the battery operating conditions to the data server at step 502. At this step, the operating system may also send a battery table selector to the data server. The battery table selector may be utilized so that the data server only sends back the specified battery tables to the mobile communication device.

At step 504, the data server receives the one or more battery operating conditions from the mobile communication device and performs a search to find matching battery operating conditions for the battery. At step 506, the data server determines whether matching battery operating conditions are stored. If matching battery operating conditions are present in the data server, then the data server generates the corresponding battery profile at step 508. Depending on the mode of operation, the data server may generate the battery profile based on a corresponding profile identified, as described in relation to FIG. 6. The data server may also generate a battery profile using the battery model as explained above with reference to FIG. 7. For either method, if the battery operating conditions received from the mobile communication device do not match operating conditions on the data server that are associated with the specific battery, then the data server generates an error message at step 510 that is sent to the mobile communication device.

If a battery profile is generated by the data server, at step 512, then the data server sends the battery profile to the mobile communication device. If the mobile communication device sent the data server a battery table selector at step 502, then the data server only sends the selected battery table, or

8

tables. At step 514, the operating system of the mobile communication device may use the battery profile to replace an existing battery profile. Likewise, if the data server only sends a battery table, the mobile communication device may only replace those tables that are received.

The method in FIG. 9 may also be configured so that the mobile communication device sends calibration information to the data server following step 514. The data server may use this calibration information to update the battery profiles so that a more accurate battery status can be calculated by the mobile communication device.

FIG. 10 is a block diagram of an example mobile device 600 that may include a system for determining the status of a battery. The mobile device 600 includes a charging subsystem 602 and a rechargeable battery 604. The charging subsystem 602 may include a battery measurement subsystem, as described herein. In addition, the rechargeable battery 604 may include an integrated memory device for storing battery deterioration information and/or other information pertaining to the battery 604. The mobile device 600 may also include a processing device 606, a communications subsystem 608, a short-range communications subsystem 610, input/output devices 612-615, memory devices 616, 618, a USB interface 620 and USB controller 622, and various other device subsystems 624.

In addition to measuring the status of a battery, the charging subsystem 602 charges the rechargeable battery 604 and provides power to the mobile device 600, either from the rechargeable battery 604 or from a USB host connected to the USB interface 620. The USB controller 622 monitors the USB data lines, and controls data communication between the processing device 606 and a USB host.

The processing device 606 controls the overall operation of the mobile device 600. Operating system software executed by the processing device 606 is preferably stored in a persistent store such as a flash memory 618, but may also be stored in other types of memory devices, such as a read only memory (ROM) or similar storage element. In addition, operating system software, specific device applications, or parts thereof, may be temporarily loaded into a volatile store, such as a random access memory (RAM) 616. Communication signals received by the mobile device 600 may also be stored to RAM 616.

The processing device 606, in addition to its operating system functions, enables execution of software applications on the device 600. A predetermined set of applications that control basic device operations, such as data and voice communications, may be installed on the device 600 during manufacture. In addition, a personal information manager (PIM) application may be installed during manufacture. The PIM is preferably capable of organizing and managing data items, such as e-mail, calendar events, voice mails, appointments, and task items. The PIM application is also preferably capable of sending and receiving data items via the wireless network 626. Preferably, the PIM data items are seamlessly integrated, synchronized and updated via the wireless network 626 with the device user's corresponding data items stored or associated with a host computer system.

Communication functions, including data and voice communications, are performed through the communication subsystem 608, and possibly through the short-range communications subsystem 610. If the mobile device 600 is enabled for two-way communications, then the communication subsystem 600 includes a receiver 628, a transmitter 630, and a processing module 632, such as a digital signal processor (DSP). In addition, the communication subsystem 608, configured as a two-way communications device, includes one or

more, preferably embedded or internal, antenna elements **634**, **636**, and local oscillators (LOs) **638**. The specific design and implementation of the communication subsystem **608** is dependent upon the communication network **626** in which the mobile device **600** is intended to operate. Network access requirements vary depending upon the type of communication system **626**.

When required network registration or activation procedures have been completed, the mobile device **600** may send and receive communication signals over the communication network **626**. Signals received by the antenna **634** through the communication network **626** are input to the receiver **628**, which may perform such common receiver functions as signal amplification, frequency down-conversion, filtering, channel selection, and analog-to-digital conversion. Analog-to-digital conversion of the received signal allows the DSP to perform more complex communication functions, such as demodulation and decoding. In a similar manner, signals to be transmitted are processed by the DSP **632**, and are then input to the transmitter **630** for digital-to-analog conversion, frequency up-conversion, filtering, amplification and transmission over the communication network **608** via the antenna **636**.

In addition to processing communication signals, the DSP **632** provides for receiver **628** and transmitter **630** control. For example, gains applied to communication signals in the receiver **628** and transmitter **630** may be adaptively controlled through automatic gain control algorithms implemented in the DSP **632**.

In a data communication mode, a received signal, such as a text message or web page download, is processed by the communication subsystem **608** and input to the processing device **606**. The received signal is then further processed by the processing device **606** for output to a display **612**, or alternatively to some other auxiliary I/O device **638**. A device user may also compose data items, such as e-mail messages, using a keyboard **613**, such as a QWERTY-style keyboard, and/or some other auxiliary I/O device **638**, such as a touchpad, a rocker switch, a thumb-wheel, or some other type of input device. The composed data items may then be transmitted over the communication network **626** via the communication subsystem **608**.

In a voice communication mode, overall operation of the device **600** is substantially similar to data communication mode, except that received signals are output to a speaker **614**, and signals for transmission are generated by a microphone **615**. Alternative voice or audio I/O subsystems, such as a voice message recording subsystem, may also be implemented on the device **600**. In addition, the display **612** may also be utilized in voice communication mode, for example to display the identity of a calling party, the duration of a voice call, or other voice call related information.

The short-range communications subsystem **610** enables communication between the mobile device **600** and other proximate systems or devices, which need not necessarily be similar devices. For example, the short-range communications subsystem **610** may include an infrared device and associated circuits and components, or a Bluetooth™ communication module to provide for communication with similarly-enabled systems and devices.

This written description uses examples to disclose the invention, including the best mode, and also to enable a person skilled in the art to make and use the invention. The patentable scope of the invention may include other examples that occur to those skilled in the art.

The invention claimed is:

1. A mobile communication device comprising:

a battery configured to power the mobile communication device;

a sensor device configured to monitor an operating condition of the battery; and

an operating system configured to:

wirelessly transmit a battery operating condition to a data server,

wirelessly receive, from the data server, a battery profile corresponding to the current battery operating condition,

measure, at said operating condition, a value relating to the battery, and

calculate battery status information from the measured value using the battery profile.

2. The mobile communication device of claim 1 wherein the battery status information is battery capacity.

3. The mobile communication device of claim 1 wherein the battery status information is usable battery capacity.

4. The mobile communication device of claim 1 wherein the battery status information is equivalent series resistance.

5. The mobile communication device of claim 1 wherein the operating system is configured to select a portion of the battery profile to be sent from the data server.

6. The mobile communication device of claim 1 wherein the operating system is configured to replace an existing battery profile with the battery profile received from the data server.

7. The mobile communication device of claim 1 wherein the operating system is configured to transmit the battery operating condition to the data server in response to a user request.

8. The mobile communication device of claim 1 wherein the operating system is configured to transmit the battery operating condition to the data server in response to a change in ambient temperature.

9. The mobile communication device of claim 1 wherein the operating system is configured to transmit the battery operating condition to the data server in response to a power-up of the communication device.

10. The mobile communication device of claim 1 wherein the operating system is configured to transmit the battery operating condition to the data server in response to a new charge cycle of the battery.

11. A data server for storing battery profiles, comprising: battery identifiers, each identifying a different battery type; battery operating conditions that include operating characteristics for each battery type; and

battery profiles, each corresponding to one of the battery identifiers and one of the battery operating conditions, the battery profiles containing information used to calculate battery status information and replace an existing battery profile on a mobile communication device;

the data server being configured to wirelessly receive a current operating condition and a current battery identifier from the mobile communication device and to wirelessly transmit a battery profile to the mobile communication device corresponding to the current operating condition and the current battery identifier.

12. The data server of claim 11 wherein the battery status information is battery capacity.

13. The data server of claim 11 wherein the battery status information is usable battery capacity.

14. The data server of claim 11 wherein the battery status information is equivalent series resistance.

11**12**

15. The data server of claim **11** wherein the data server is configured to store the current battery operating condition received from the mobile communication device.

16. The data server of claim **11** wherein the profiles include electrical current verses transmit power.

5

17. The data server of claim **11** wherein the profiles include battery capacity verses battery voltage.

18. The data server of claim **11** wherein the profiles include battery capacity compensation factor verses temperature.

19. The data server of claim **11** wherein the profiles include equivalent series resistance compensation factor verses temperature.

10

20. The data server of claim **11** wherein the current operating condition is state of charge.
